Manuscript Proofs
Your manuscript has been edited for RSNA style and usage, which are based on widely accepted conventions of grammar and the *American Medical Association Manual of Style*. Please read the attached copy carefully to ensure that your meaning has been retained.

Author Queries
Queries are indicated in the margins and listed at the end of the page proofs. Please keep your changes to a minimum and correct only inaccurate items. Figure sizing and many layout decisions have already been made. Annotate the PDF proofs with your corrections using Acrobat comment and markup tools. *We recommend that you retain a copy of the corrected manuscript.*

Figures
Check the fidelity and orientation of the figures. Check the placement of keys (arrows, letters, etc) on the illustrations; if repositioning is necessary, indicate the proper location on the figure itself. Illustrations become property of RSNA and will be stored for 2 years after publication. They will be returned only upon written request from the corresponding author.

Return and Publication
Return corrected page proofs within 72 hours by uploading the proofs to The Author Center. Your paper cannot be published until we have received your corrections. *Do not impose any security on your document.*

Reprints
Please e-mail inquiries regarding reprints to reprints@rsna.org. Specify the number of copies and color choice (black & white or color).

Interstitial Myocardial Fibrosis Assessed as Extracellular Volume Fraction with Low-Radiation-Dose Cardiac CT

**Purpose:**
To develop a cardiac computed tomographic (CT) method with which to determine extracellular volume (ECV) fraction, with cardiac magnetic resonance (MR) imaging as the reference standard.

**Materials and Methods:**
Study participants provided written informed consent to participate in this institutional review board–approved study. ECV was measured in healthy subjects and patients with heart failure by using cardiac CT and cardiac MR imaging. Paired Student t test, linear regression analysis, and Pearson correlation analysis were used to determine the relationship between cardiac CT and MR imaging ECV values and clinical parameters.

**Results:**
Twenty-four subjects were studied. There was good correlation between myocardial ECV measured at cardiac MR imaging and that measured at cardiac CT ($r = 0.82$, $P < .001$). As expected, ECV was higher in patients with heart failure than in healthy control subjects for both cardiac CT and cardiac MR imaging ($P = .03$, respectively). For both cardiac MR imaging and cardiac CT, ECV was positively associated with end diastolic and end systolic volume and inversely related to ejection fraction ($P < .05$ for all). Mean radiation dose was $1.98 \text{ mSv} \pm 0.16$ (standard deviation) for each cardiac CT acquisition.

**Conclusion:**
ECV at cardiac CT and that at cardiac MR imaging showed good correlation, suggesting the potential for myocardial tissue characterization with cardiac CT.

Ocular myocardial scar after myocardial infarction can be readily identified with cardiac magnetic resonance (MR) imaging with delayed gadolinium-enhanced techniques (1). Cardiac MR imaging has been well validated and enables quantification of myocardial scar mass in comparison with overall mass of the myocardium. Unfortunately, cardiac MR imaging is not widely available and has its own contraindications and limitations. Cardiac computed tomography (CT) is well tolerated by patients and has been validated for use in the detection of focal myocardial scar (2–6).

Diffuse interstitial myocardial fibrosis is an increasingly recognized disease process common to a variety of cardiomyopathies and heart failure. T1 mapping with contrast material–enhanced cardiac MR imaging has been developed to enable quantification of diffusely abnormal myocardial signal intensity (7–12). Myocardial extracellular volume (ECV) fraction represents the equilibrium distribution of gadolinium in the blood and myocardium and is derived from T1 measurements. ECV is increased in association with diffuse myocardial fibrosis, a hallmark of pathologic remodeling (13–15). Cardiac MR imaging T1 mapping with ECV determination has been validated in multiple conditions, including heart failure secondary to ischemic and nonischemic cardiomyopathies, aortic valve disease, and hypertrophic cardiomyopathy (7,9,12,16–19).

With the increasing use of cardiac CT and because myocardial fibrosis is central to many disease processes involving the myocardium, we sought to develop a cardiac CT method with which to determine ECV fraction. We used cardiac MR imaging as the reference standard for comparison.

**Materials and Methods**

**Study Population**

This single-center study was approved by National Institutes of Health Clinical Center institutional review board. All study participants provided written informed consent and completed both cardiac CT and cardiac MR imaging studies on the same day within a 4-hour window. From August 2010 to October 2011, 28 participants were enrolled. Patients with New York Heart Association, or NYHA, grade II or greater heart failure and either left ventricular ejection fraction less than 40% or diagnosis of diastolic dysfunction and left ventricular ejection fraction greater than 50% were included, as were healthy individuals. Healthy subjects had no history of clinical cardiovascular disease. Normal left and right ventricular volumes and systolic functions were confirmed at cardiac MR imaging. All clinical examinations and laboratory tests were performed no more than 7 days before cardiac CT (Fig 1).

**Cardiac MR Imaging Protocol**

Images were obtained in all study subjects with a 3-T imager (Verio; Siemens, Erlangen, Germany) with a 32-channel cardiovascular array coil (In Vivo, Orlando, Fl). An 11-heart-beat modified Look Locker sequence with inversion recovery was used for cardiac MR imaging T1 measurement, as described previously (20). Scanning parameters were as follows: repetition time msec/echo time msec/minimum inversion time msec, 1.9/1.0/110.0; inversion time increment, 80.0 msec; field of view, 290–360 mm; readout resolution, 192;

**Implication for Patient Care**

ECV measured with cardiac CT represents a new approach toward the clinical assessment of diffuse myocardial fibrosis.

**Funding:**

This research was supported by the National Institutes of Health intramural program.

Potential conflicts of interest are listed at the end of this article.
parameters were as follows: tube voltage, 120 kV; tube current, 300 mA; and section thickness, 3 mm (22). Coronary CT angiography was performed during intravenous infusion of 125 mL ± 24 (mean ± standard deviation) of iopamidol (Isovue 370; Bracco Diagnostics) at a rate of 4–5 mL/sec by using the following parameters: For subjects with a heart rate of less than 66 beats per minute, we used prospective electrocardiographic gating at 70%–80% of one R-R interval and x-ray exposure times ranging from 0.423 to 0.350 second. For subjects with a heart rate of at least 66 beats per minute, we used prospective electrocardiographic gating at 40%–80% of two R-R intervals and x-ray exposure times ranging from 0.714 second to 1.174 seconds. Additional parameters were as follows: tube voltage, 120 kV, tube current, 300–580 mA depending on body mass index and sex; gantry rotation speed, 0.35 seconds; section thickness, 0.5 mm; and scanning range, 128–160 mm. After a 10-minute delay, postcontrast cardiac CT was performed with parameters identical to those used for the precontrast calcium score scan.

Data Analysis
T1 maps from cardiac MR imaging data were calculated by using MRmap software (23). For extraction of myocardial T1 values, regions of interest for signal intensity measurement were drawn in the anterior and anterolateral segments of myocardial and blood pool contours by using QMass software (version 7.2; Medis, Leiden, the Netherlands) (Fig 2).

Cardiac CT Protocol
All study participants were examined with a 320-detector row CT scanner (Aquilion One; Toshiba Medical Systems, Tustin, Calif) after cardiac MR imaging. A precontrast calcium score–type acquisition was performed with prospective electrocardiographic gating with a 400-msec single gantry rotation during an inspiratory breath hold that enables image acquisition in a single cardiac phase. Scanning
Results are from logistic regression analysis. ECV fraction was calculated with the following equation: $E CV = \frac{(\Delta R_1)_m}{R_1}$, where $R_1_m$ is the change in relaxivity, $R_1$ is the hematocrit level, and $\Delta R_1$ is the change in relaxivity. The change in relaxivity, $(1/T_1)$, was determined with the following equation: $(1/T_1) = R_1^m - R_1^p$, where $R_1^p$ and $R_1^m$ are $R_1$ after and before gadolinium chelate administration, respectively (24–26).

and before administration of iodinated contrast material, respectively. Coronary calcium score was quantified by using the Agatston method (28). Coronary calcium and CT angiographic data were analyzed by using Vitrea software, as described previously. Two observers (N.K., M.S.N.; 2 and 7 years of experience in cardiovascular imaging, respectively) evaluated the cardiac CT data and were blinded to the clinical data.

**Statistical Analysis**

The paired Student t test was used to determine significant differences between cardiac CT and cardiac MR imaging ECV values. Linear regression analysis and Pearson correlation were also used to examine the relationship between two methods by using ECV at cardiac MR imaging as the predictor variable and ECV at cardiac CT as the dependent variable. The Bland-Altman method was used to calculate bias and limits of agreement. Inter- and intraobserver variability were assessed with Pearson correlation as the standard deviation of the difference (SDD) between two readings. The coefficient of variation was calculated by dividing the SDD by the average of the two readings. Coronary calcium was treated as the log of the calcium score plus one. P < .05 was considered indicative of a significant difference.

**Results**

The average duration of the examination was 47 minutes ± 5 for cardiac MR imaging and 13 minutes ± 1.5 for cardiac CT. Four participants were excluded: Two had atrial fibrillation, one had shortness of breath, and one had a CT protocol violation. A total of 24 participants were included for analysis; 13 subjects had heart failure, and 11 were healthy. The mean age in this population was 63.2 years ± 10 (range, 45–95 years). Male subjects had a mean age of 60.7 years ± 6.4 (range, 46–72 years), and female subjects had a mean age of 66.6 years ± 13.7 (range, 45–95 years). There was no significant difference between male and female groups in this study (P = .23). Participant characteristics are summarized in Table 1.

Cardiac MR imaging data were available for analysis in 136 of 144 T1 maps at the base, middle, and apical levels on pre- and postcontrast images, yielding 65 of 72 ECV values with cardiac MR imaging. Seven ECV maps could not be analyzed because of respiratory and cardiac-gating artifacts on cardiac MR images. A total of 68 of 72 ECV values were measured with cardiac CT. Four ECV maps obtained with cardiac CT were excluded because of attenuation artifacts in the area of interest.
ECV values showed good correlation between the two methods ($r = 0.82$, $P < .001$) (Fig 3a). ECV values were slightly lower when measured with cardiac MR imaging as opposed to cardiac CT (28.6% ± 4.4 vs 31.6% ± 5.1, $P = .03$). The 95% limits of agreement between the two methods ranged from −2.82% to 8.85%. A small bias (3.01%) toward higher ECV was detected for cardiac MR imaging. As expected, cardiac MR imaging–derived ECV was lower in the healthy group than in the heart failure group (26.6% ± 2.9 vs 30.3% ± 4.9, respectively; $P = .03$). For cardiac CT, ECV was also lower for the healthy subjects than for the patients with heart failure (29.3% ± 2.7 vs 33.5% ± 5.9, respectively; $P = .03$) (Fig 3b). End-diastolic volume, end-systolic volume, and time to peak filling rate (greater time to peak filling rate indicated diastolic dysfunction) were positively associated with ECV ($P < .001$ for all), while ejection fraction was inversely correlated with ECV for both cardiac MR imaging and cardiac CT ($P < .05$ for all; Table 2).

The correlation coefficients for inter- and intraobserver agreement for cardiac CT were 0.95 (12.2% SDD) and 0.98 (7.5% SDD), respectively, for myocardium density measurement and 0.99 (5.1% SDD) and 0.99 (2.8% SDD), respectively, for blood pool density measurement. For cardiac MR imaging, the correlation coefficients for inter- and intraobserver agreement were 0.98 (7.9% SDD) and 0.98 (7.0% SDD), respectively, for myocardium and 0.99 (4.0% SDD) and 0.99 (2.9% SDD), respectively, for blood pool relaxivity measurements. The average radiation dose was 1.98 mSv ± 0.16 (average dose-length product, 141.5 mGy · cm ± 11.7) for both baseline and delayed ECV measurements. The average radiation dose was 3.14 mSv ± 0.82 (average dose-length product, 221.1 mGy · cm ± 59.5) for cardiac CT angiography.

### Discussion

Cardiac MR imaging and cardiac CT have been used to detect areas of focal myocardial scarring that is typically related to myocardial infarction. Recently, innovations in cardiac MR imaging technique have enabled assessment of diffuse myocardial fibrosis associated with heart failure or cardiomyopathy. By using a relatively low-radiation-dose method, ECV values for cardiac CT were shown to be comparable to those obtained with cardiac MR imaging. ECV values were elevated in subjects with heart failure; greater ECV values were associated with reduced ejection fraction and increased end-systolic and end-diastolic volumes.

ECV fraction has been shown to be a reproducible and novel index with which to assess fibrosis (11,13,24–26,29). A wide range of disease conditions, including acute and chronic myocardial infarction (30,31), chronic aortic regurgitation (32), heart failure (9), dilated cardiomyopathy (16), and hypertrophic cardiomyopathy (17) have altered ECV values at cardiac MR imaging. Iles et al (9) showed abnormal diastolic function associated with increased

† Results are from logistic regression analysis.
collagen content. In the current study, decreased myocardial function and abnormal diastolic function were also associated with increased ECV.

There were several limitations to this study. First, we included only the anterior and anterolateral segments of the myocardium in the analysis. These regions were reliably identified on precontrast cardiac CT images and showed good contrast between adjacent pericardium and lung tissue. Second, cardiac CT ECV validation was based on cardiac MR imaging findings rather than on histologic specimens. Subjects in this study were not eligible for tissue biopsy. In addition, premortem human data based on tissue biopsy were limited by very small tissue specimens that were subject to sampling error. However, previous studies have shown consistent histologic correlation between cardiac MR imaging–derived T1 and ECV values in both human and animal studies (9, 10, 25, 26). The cardiac CT method we described requires additional radiation (mean, 1.9 mSv). Lower-dose cardiac CT techniques, such as iterative image reconstruction, were not available at the time of protocol development.

In conclusion, we have described the assessment of myocardial fibrosis via ECV determination with cardiac CT. ECV measured with cardiac CT shows good reproducibility and correlates well with ECV measured with T1-mapping cardiac MR imaging–determined values, representing a potential new approach toward the clinical assessment of diffuse myocardial fibrosis.
